

# Measurements from Linear Array Camera Images

Satellite control is the key to accurate measurements.

NEW SENSOR SYSTEMS based on charge transfer device (CTD) linear array technology are contemplated for use in planned or proposed satellite missions such as SPOT,<sup>1</sup> Stereosat,<sup>2</sup> Marine Observation Satellite (MOS),<sup>3</sup> and Mapsat,<sup>4</sup> but methods of extracting X, Y, Z terrain information from the image data have received relatively little attention. These missions will provide cartographers, geographers, geologists, forest-

the orbit path as a series of successive lines or strips as a function of spacecraft velocity ( $v$ ) and time ( $t$ ),<sup>5</sup> i.e.,

$$\Delta x = v \cdot \Delta t \quad (1)$$

where

$\Delta x$  = along track distance increment,  
 $\Delta t$  = time increment, and  
 $v$  = ground velocity ( $\sim 6.8 \text{ km}^{-1}$ ).

---

**ABSTRACT:** *Pushbroom camera systems are contemplated for use on a number of satellite missions in the early 1980's, including SPOT, Stereosat, Marine Observation Satellite, and Mapsat. In order to obtain accurate planimetric and height measurements from these images, however, consideration must be given to the unique geometric characteristics of the linear array camera system. Planimetric measurements from near-orthogonal vertical images may be undertaken with the scale formula employed for vertical aerial photographs. However, height measurements from images recorded by a proposed three-camera Stereosat system require consideration of the parallel ray geometry. Differences in x parallax ( $\Delta p$ ) are a function of elevation, time, and camera orientation angle ( $\alpha$ ). For an along track convergent camera configuration, height differences ( $\Delta h$ ) may be closely approximated with the equation,  $\Delta h = (\Delta p/2 \tan \alpha) \cdot SF$ . Accuracy of measurements will be significantly influenced by variations in sensor attitude and velocity over the time interval required to record the pictures and by pointing errors due to tilt.*

---

ers, and other scientists with high resolution data (10 to 20 m ffov or instantaneous field-of-view) of unusual geometric characteristics in both monoscopic and stereoscopic formats. In this brief note some of the possibilities for deriving simple planimetric and height measurements from linear array camera images are considered.

The linear array camera operating in the "pushbroom" mode records the terrain along

Cross track coverage is limited by the number of detectors in the line array and the field-of-view (FOV) of the camera lens. Along track and cross track coverage are shown in Figure 1. No moving camera parts or scanning mechanisms are required.

Planimetric ( $x, y$ ) measurements may be obtained from vertical images with the geometric relationships employed with vertical aerial photographs, i.e.,

$$\begin{aligned}
 & \frac{\text{focal length } (f)}{\text{spacecraft altitude } (H)} \\
 = & \frac{\text{image distance}}{\text{object distance}} \\
 = & \frac{1}{\text{scale factor } (SF)} \quad (1)
 \end{aligned}$$

It should be realized, however, that, although the image is recorded as a near orthogonal projection in the  $x$  (along track) direction, it is comprised of a series of parallel perspective projections (one for each strip) in the  $y$  (cross-track) direction. Small displacements in the  $y$  direction due to relief and Earth curvature can be ignored unless (1) camera fov's of more than about 5 degrees are used; (2) terrain is extremely rugged (e.g., greater than 1000 m relief); (3) images are greatly enlarged prior to analysis; and/or (4) highly analytical measurement techniques are employed. As an example, consider the proposed characteristics of the vertical Stereosat camera:

$$\begin{aligned}
 f &= 705 \text{ mm} \\
 H &= 705 \text{ km} \\
 \text{FOV} &= 61.4 \text{ km}
 \end{aligned}$$

$$\text{Scale at focal plane} = 1:1,000,000$$

With relief ( $\Delta h$ ) of 1000 m along a specific strip, the maximum displacement ( $\Delta y$ ) at the lateral margin of the vertical image will be

$$\begin{aligned}
 \Delta y &= \frac{\Delta h}{H} \cdot y \quad (2) \\
 &= \frac{1,000}{705,000} \cdot 30.7 \text{ mm} \\
 &= 0.044 \text{ mm}
 \end{aligned}$$

FIG. 1. Along track ( $x$ ) coverage is a function of spacecraft velocity and time, whereas cross track ( $y$ ) coverage depends on the camera fov and the number of detectors.

With a  $10\times$  image enlargement,  $\Delta y$  is increased to 0.44 mm, which is still rather insignificant for the majority of applications. Thus, in most instances, the vertical image can be considered a map and distances scaled accordingly.

Height measurements, however, present a more serious problem. In order to obtain  $x$  parallax and the differences in  $x$  parallax required for the perception of terrain relief in the stereo mode, two approaches are proposed: (1) images recorded from adjacent orbits by cameras equipped with rotatable mirrors to control the pointing direction (spot); or (2) images recorded successively along the orbit path from fixed forward, vertical, and aft pointing cameras (Stereosat). By recording data from adjacent orbits the spot system relies on perspective geometry to develop parallaxes, whereas the three-camera system proposed for Stereosat makes use of parallel ray geometry. It is the latter system which is examined.

In the three-camera system proposed for Stereosat, forward and aft pointing cameras oriented  $26.57$  degrees ( $\alpha$ ) from the object vertical in the along-track direction and a vertical camera orthogonal to the terrain will be employed to obtain stereoscopic coverage. Base-to-height ratios of 0.49 (vertical and fore/aft) and 1.0 (fore and aft) are planned from the nominal altitude of 705 km (775 km slant range for forward and aft cameras).\* With this arrangement, the  $x$  coordinates in the image planes of the forward and aft pointing cameras are a function of elevation and time (Figure 2), and height difference ( $\Delta h$ ) measurements are closely approximated with the following equation:†

$$\Delta h \approx \frac{x_1 - x_2}{2 \tan \alpha} \cdot SF \text{ or } \Delta h \approx \frac{\Delta p}{2 \tan \alpha} \cdot SF \quad (3)$$

where

$$\begin{aligned}
 x_1, x_2 &= x \text{ parallaxes measured in the} \\
 & \quad \text{image plane,} \\
 \Delta p &= \text{difference in } x \text{ parallax,} \\
 \alpha &= \text{camera orientation angle, and} \\
 SF &= \text{image scale factor.}
 \end{aligned}$$

\* The focal lengths for the vertical and oblique cameras are 705 and 775 mm, respectively. However, the altitude (705 km) may be changed, requiring a modification of the focal lengths to achieve a scale of 1:1,000,000 at the focal plane.

† In order to obtain more exact values for  $\Delta h$ , a small correction must be introduced to account for the curved trajectory of the satellite. For the referenced fore and aft stereopair, the denominator  $2 \tan \alpha$  must be modified to  $1.972 \tan \alpha$ .

FIG. 2. For the above three-camera configuration,  $\Delta h$  is a function of  $\alpha$  and of the time interval ( $\Delta t$ ) required to record both the top and bottom of the object. In the forward/aft stereopair  $\Delta t$  is represented by  $(x_1 - x_2) = \Delta p$ . A dashed line indicates the satellite's trajectory.

Similar relationships were previously developed for the stereoscopic strip camera.<sup>6</sup> Unlike the strip camera, however, the pushbroom system is recording data along a single cross-track line at any given instant in time without film movement (or IMC) to complicate the geometry. Consequently, the quantity  $(x_1 - x_2)$  as measured with either a mirror stereoscope and parallax bar or a comparator may be taken as the difference in parallax ( $\Delta p$ ).

For heighting, the forward and aft stereopairs will give superior results since  $2 \tan \alpha$  for a 26.57 degree angle ( $\alpha$ ) is 1.0. Thus, at the image scale,  $\Delta x = \Delta p \approx \Delta h$ , which is a convenient relationship. Correspondingly, any measurement error in  $\Delta p$  causes an equivalent error in  $\Delta h$ . If the vertical image is employed with either the forward or aft image to form the stereopair, the denominator of Equation 3 becomes  $\tan \alpha$  and an error in  $\Delta p$  causes an error of approximately twice that magnitude in  $\Delta h$ . The relationship between  $\alpha$ ,  $\Delta p$  error, and  $\Delta h$  error is developed further in Figure 3.

Of course, in a pushbroom system the stereo images are generated continuously, and approximately 92 seconds are required to record a stereo-triplet in the proposed Stereosat configuration. Obviously, any variation in the attitude of the satellite over this rather long interval will produce planimetric and vertical displacements. State-of-the-art attitude correction rates range from about  $10^{-4}$  deg/sec to  $10^{-5}$  deg/sec, which over the above time interval could result in height errors of between approximately 125 and 10 m. Consequently, the attitude control/recovery system is an extremely important ingredient

FIG. 3. The precision in setting the floating mark at the top and bottom of an imaged object results in an error,  $\Delta p_\sigma = \sqrt{\sigma_a^2 + \sigma_b^2}$ . A representative value of  $\Delta p_\sigma = \pm 14 \mu\text{m}$  is assumed. This error ( $\Delta p_\sigma$ ) may then be converted to a height error ( $\Delta h_\sigma$ ) and plotted as a function of the angle ( $\alpha$ ). A stereopair comprised of fore and aft images minimizes the influence of pointing errors, as does the enlargement of images prior to measurement.

of spacecraft designed to provide data for applications requiring X, Y, Z terrain measurements.

Pointing errors or bias due to a constant tilt will introduce a systematic datum error which can be corrected with the aid of ground control, attitude information, and appropriate adjustment procedures.<sup>7</sup> Other errors introduced by variations in spacecraft velocity and Earth rotation can be compensated for with the aid of timing marks and appropriate spacecraft controls.

In conclusion, sophisticated processing procedures undoubtedly will be developed to extract terrain coordinates from digital data recorded by pushbroom sensors,<sup>8</sup> and, as with Landsat, the full potential of the data probably will not be realized until after it becomes available. Nevertheless, scientists should be able to utilize conventional measurement techniques to derive useful X, Y, Z terrain information from images generated by pushbroom sensor systems.

### Notice to Contributors

1. Manuscripts should be typed, double-spaced on  $8\frac{1}{2} \times 11$  or  $8 \times 10\frac{1}{2}$  white bond, on *one* side only. References, footnotes, captions—everything should be double-spaced. Margins should be  $1\frac{1}{2}$  inches.
2. Ordinarily *two* copies of the manuscript and two sets of illustrations should be submitted where the second set of illustrations need not be prime quality; EXCEPT that *five* copies of papers on Remote Sensing and Photointerpretation are needed, all with prime quality illustrations to facilitate the review process.
3. Each article should include an abstract, which is a *digest* of the article. An abstract should be 100 to 150 words in length.
4. Tables should be designed to fit into a width no more than five inches.
5. Illustrations should not be more than twice the final size: *glossy* prints of photos should be submitted. Lettering should be neat, and designed for the reduction anticipated. Please include a separate list of captions.
6. Formulas should be expressed as simply as possible, keeping in mind the difficulties and limitations encountered in setting type.
